What are sets?

- A set is a collection of objects of the same type that has the following two properties:
  - there are no duplicates in the collection
  - the order of the objects in the collection is irrelevant.

- \{6,9,11,-5\} and \{11,9,6,-5\} are equivalent.

- There is no first element, and no successor of 9.

Set Operations

- **Set construction**
  - the empty set (0 elements in the set)
- **isEmpty()**
  - True, if the set is empty; false, otherwise.
- **Insert(element)**
  - If element is already in the set, do nothing; otherwise add it to the set
- **Delete(element)**
  - If element is not a member of the set, do nothing; otherwise remove it from the set.

- **Member(element): boolean**
  - True, if element is a member of the set; false, otherwise
- **Union(Set1,Set2): Set**
  - returns a Set containing all elements of the two Sets, no duplications.
- **Intersection(Set1,Set2): Set**
  - returns a Set containing all elements common to both sets.
Set Operations

- **Difference(Set1,Set2): Set**
  - returns a Set containing all elements of the first set except for the elements that are in common with the second set.

- **Subset(Set1,Set2): boolean**
  - True, if Set1 is a subset of Set2 (if all elements of the Set1 are also elements of Set2).

- **Equals(Set1,Set2): boolean**
  - True, if both sets contain exactly the same elements.

Implementation

- **Array of elements implementation**
  - each element of the set will occupy a position in the array.
  - the member (find) operation will be inefficient, must use linear search.
    
    ```
    class IntSet {
        int count;    //number of elements in the set, set to 0 in constr
        int intSet[100]; //stores the elements in positions 0..count
    }
    
    void insert(int x) {
        if (!member(x) && count<100) {
            intSet[count] = x;
            count++;
        }
    }
    ```

- **Array of elements implementation: member**
  ```
  bool member(int x) {
      for (int i=0; i<count; i++) {
          if (intSet[i]==x) return true;
      }
      return false;
  }
  ```

- **Array of elements implementation: union**
  ```
  IntSet operator+(IntSet rhs) {
      IntSet newSet;
      for (int i=0; i<count; i++) { 
          newSet.insert(intSet[i]);
      }
      for (int i=0; i<rhs.count; i++)
          newSet.insert(rhs.intSet[i]);
      return newSet;
  }
  ```

- **Exercise: implement all of the set operations for the IntSet.**

Implementation

- **Boolean array implementation**
  - size of the array must be equal to number of all possible elements (the universe).
    ```
    bool daysOfWeek[7] = {false}; //sets all elements to false
    ```

- **Here is the set {Monday, Wednesday, Friday}:**

<table>
<thead>
<tr>
<th>FALSE</th>
<th>TRUE</th>
<th>FALSE</th>
<th>TRUE</th>
<th>FALSE</th>
<th>TRUE</th>
<th>FALSE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sunday</td>
<td>Monday</td>
<td>Tuesday</td>
<td>Wednesday</td>
<td>Thursday</td>
<td>Friday</td>
<td>Saturday</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>4</td>
<td>5</td>
<td>6</td>
</tr>
</tbody>
</table>

- if `daysOfWeek[1]` is true, then Monday is in the set.
Implementation

- Boolean array implementation
- need a mapping function to convert an element of the universe to a position in the array

```c
int map(string x) {
    if (x == "Sunday") return 0;
    if (x == "Monday") return 1;
    if (x == "Tuesday") return 2;
    if (x == "Wednesday") return 3;
    if (x == "Thursday") return 4;
    if (x == "Friday") return 5;
    if (x == "Saturday") return 6;
}
```

- if `daysOfWeek[startOfWeek("Monday")].` is true, then Monday is in the Set.

What are hash tables?

- A Hash Table is used to implement a set (or a search table), providing basic operations in constant time (no loops/recursion):
  - insert
  - delete (optional)
  - find (also called "member")
  - makeEmpty (need not be constant time)
- It uses a function that maps an object in the set (a key) to its location in the table.
- The function is called a hash function.

Using a hash function

HandyParts company makes no more than 100 different parts. But the parts all have four digit numbers.

This hash function can be used to store and retrieve parts in an array.

Hash(partNum) = partNum % 100

Use the hash function to place the element with part number 5502 in the array.
Placing elements in the array

Next place part number 6702 in the array.

Hash(partNum) = partNum % 100

6702 % 100 = 2

But values[2] is already occupied.

COLLISION OCCURS

How to resolve the collision?

One way is by linear probing. This uses the following function

(HashValue + 1) % 100

repeatedly until an empty location is found for part number 6702.

Collision resolved

(Hash(6702) + 1) % 100 = 3

But values[3] is already occupied.

Collision resolved

Part 6702 is placed at the location with index 4.

Where would the part with number 4598 be placed using linear probing?
Hashing concepts

- **Hash Table**: (usually an array) where objects are stored according to their key
  - key: attribute of an object used for searching/sorting
  - number of valid keys usually greater than number of slots in the table
  - number of keys in use usually much smaller than table size.

- **Hash function**: maps a key to a Table index
- **Collision**: when two separate keys hash to the same location

Implementation

- Simple array implementation:
  - keys are ints, all greater than or equal to 0:
    ```cpp
class HashTable {
private:
    int *array; // array of int elements
    int size; // use -1 to indicate empty slot
    int hash (int key); // maps key to position in array
public:
    HashTable (int size); //initialize all elements to -1
    ~HashTable();
    bool find(int); //return true if int in table
    void insert (int); //add int to table
    void display(); //show elements in table
};
```

Collision Resolution:

- **Linear Probing**
  - Insert: When there is a collision, search sequentially for the next open slot (-1)
    - Put the value in the table at that position
  - Find: if the key is not at the hashed location, keep searching sequentially for it.
    - if it reaches an open slot (-1), the key is not found
  - Remove: if the key is not at the hashed location, keep searching sequentially for it.
    - if the key is found, set the status to -1
  - Problem: Removing an element in the middle of a chain. The Find method needs to know to keep searching to the end of the chain.
Collision Resolution: Separate chaining

- Use an array of linked lists for the hash table
- Each linked list contains all objects that hashed to that location
  - no collisions

Hash function is still: \( h(K) = K \mod 10 \)

Separate Chaining

- To insert a an object:
  - compute hash(k)
  - if the object is not already in the list at that location, insert the object into the list.
- To find an object:
  - compute hash(k)
  - search the linked list there for the key of the object
- To delete an object:
  - compute hash(k)
  - search the linked list there for the key of the object
  - if found, remove it

Implementation

- Array of linked lists implementation
  - The data structure:

```cpp
class ChainedTable {
private:
    static const int SIZE = 10;
    struct Node {
        int key;
        Node* nextNode;
    }
    Node* table[SIZE]; //array of pointers to Nodes
    int hash(int key); // maps key to position in array
public:
    ChainedTable(); //inits all pointers in array to NULL
    bool find(int); //return true if int in table
    void insert(int); //add int to table
    ...}
```
